實價收益 — the visible range of Taiwan's rental yield

A rental yield needs a sale price and a rent for the same building. Taiwan's 實價登錄 publishes both. For most buildings it publishes only one.

Two-page brief • paper edition v1.2 (2026-11-04) • payload v2.11 • window 112S4–115S2

2.55%	1.73%	6.25%	9,843
median gross yield 95% CI 2.52–2.56	median net yield 95% CI 1.72–1.75	of 157,407 buildings that sold, priceable	matched buildings 143,297 sale–lease pairs

Method

Pair a registered sale with a registered lease in the same building within four quarters, and a gross yield falls out with no modelling. Done nationally over 11 quarters: 143,297 pairs across 9,843 buildings. Every headline is a median of per-building medians, never per pair — pairs concentrate in mega-towers, and the pair-weighted figure (2.79%) overweights exactly the least typical buildings. Intervals are a two-stage bootstrap over buildings then pairs; net deducts four costs, each sourced or bounded.

The finding is the denominator

Those medians describe **9,843 of 157,407** buildings that sold — **6.25%**. Remove every quality filter this project applies and the registry's structural ceiling is **24.20%**, because 77% of the loss is the registry itself: a lease that was never filed cannot be recovered by better cleaning.

And matchability is itself selective. You can price one apartment tower in 9 and one walk-up in 65. Walk-ups are 31.20% of the buildings that sell and 7.70% of those you can measure. The buildings you can see are **8.2% dearer per 坪** and **12 years newer** than the ones you cannot.

So the number is replaced by a range — and the range is honest about its assumption

Assuming nothing about the unseen, the median of all 157,407 buildings lies in **[0.30%, 12.00%]**. Assuming the unseen resemble seen buildings of the same type and price decile, **[1.90%, 4.26%]**. Every rung between is published, including one that makes the interval wider and is kept because it fails.

The one number here that is not good news

That resemblance assumption is tested, and it half fails. Conditioning on type and price decile absorbs 77% of the age gap between matched and unmatched buildings — but it makes the size gap worse, from -0.22 to -0.53 standard deviations, with 26 of 30 cells unbalanced. The cells are cut on price per 坪 and 坪 is that ratio's denominator, so banding on it frees the size gap instead of closing it. The interval is a stated-assumption interval, not a validated one — and it cannot be repaired by conditioning further: at 6.25% coverage the cells run out of buildings first.

Why it cannot be narrowed. A median's worst-case interval only leaves the support band once more than 50% of the population is observed, and this registry can never show more than 24.20%. The width is a property of the registry, not of the cleaning.

Against the figure in circulation

Chang and Chen (2018) report a gross rent multiplier of 64 for Taiwan and a yield of 1.57%; the stated source of that table is Global Property Guide, a commercial listings aggregator computing median asking rent over median list price. So the peer-reviewed Taiwan number and the consumer-facing one are the same number, and neither is built on transaction data. City by city, against the five both cover:

City	This work (transacted)	95% CI	buildings	Listings (June 2026)	diff
新北市	2.26%	2.23–2.29	2,583	2.19%	+0.07pp
高雄市	2.91%	2.86–2.93	1,980	2.57%	+0.34pp
臺北市	2.08%	2.03–2.12	1,616	1.97%	+0.11pp
桃園市	2.56%	2.48–2.63	949	2.44%	+0.12pp
臺南市	3.07%	2.94–3.14	792	2.12%	+0.95pp

Higher in all five, widening going south — 臺南市 differs by +0.95pp. Indicative, not like-for-like: different footprints, units and windows. Taipei has three independent estimates, agreeing to about a tenth of a point.

What was withdrawn

- **The founding hypothesis is unanswerable.** Walk-ups out-yield towers and the sign survives every control, but matched towers depart from their own population far more than matched walk-ups do, and two separately skewed samples cannot settle a population question. Its proposed mechanism is separately falsified: where the modelled fee is zero, the gap stays.
- **The transit gradient is retracted.** It survived only if 輕軌 did not count as a station, and vanished entirely in Kaohsiung.
- **"One building in 1,086" is withdrawn.** It divided 棟 by 建號 — two different units.

Every figure above is read from housing_data.json at build time, whose SHA-256 is pinned beside it, and the payload hashes every source archive the build read. **github.com/Stanley0210/taiwan-rental-yield · doi.org/10.5281/zenodo.23902646** · full report 27pp, English and 中文.

The three questions I would most like answered

1 · Coverage. Does 實價登錄 really receive only leases filed through licensed rental-service and brokerage firms? That rule carries 72 of the 94 percentage points of non-coverage — the load-bearing fact here.
2 · Conditioning. Given the balance result, is there a conditioning set this registry supports that beats type × price decile — or is partial identification the end of the road?
3 · The cost model. Does 1.73% net match what practitioners see, and is charging a management fee only where a lease records on-site staff defensible?
